### Abstract

Economic injury and economic threshold levels were estimated for the two spotted spider mite, *Tetranychus cucurbitacearum* (Sayed) (Acari, Tetranychidae) on soybean plants. An attempt was made to determine, mathematically, the point at which a significant reduction occurs in the yield of soybean at different levels of infestation by the two spotted spider mite, *T. cucurbitacearum*. For this purpose, counts were taken during each of the main three annual peaks of this mite infestation over two seasons of (2015 and 2016). The obtained results indicated that the mean values of economic injury level were 28.97 and 22.01 individuals / leaflet, while mean values of economic threshold levels were 32.05 and 21.23 individuals / leaflet during 2015 and 2016 seasons, respectively, while the general mean of economic threshold and economic injury levels were 21.23 individuals per leaflet and 18.21 individuals per leaflet, respectively.

**Key words:** Acari, spider mite, *Tetranychus cucurbitacearum*, damage, economic threshold, injury level.

### Introduction

Among phytophagous mites, the two-spotted spider mite *Tetranychus cucurbitacearum*, is the most important agricultural pests, not only because of the damage that it causes, but also because it has a wide host range. Infests many commercial crops such as leafy greens, cotton, green beans, and soybeans (Gallo *et al.*, 2002).

Although the spider mite is considered as an occasional pest of soybeans, this arthropod species has increased in occurrence. The increase in reports of this soybean pest is probably related to the more common use of magnifying glasses to identify pests in the field, and at the same time, the presence of two-spotted spider mites on leaves has alerted the agricultural community to the problem (Haile and Higley, 2003).

According to Guedes *et al.*, (2007), many factors may be contributed to the increases in spider mite populations in soybeans, mainly changes in the tillage system, such as weed control by the use of a genetically modified, glyphosate-tolerant variety, the commercial herbicide formulation which contains surfactants that may have an indirect effect on spider mites; the occurrence of soybean rust, which results in increased use of fungicides reducing the entomopathogenic fungi that regulate the spider-mite population and the intensive use of nonselective insecticides or acaricides.

Among the inappropriate insecticides are pyrethroids, which may contribute to spider-mite outbreaks, causing instability, increasing their incidence on plants and increasing the severity of symptoms caused by the mites (Degrande, 1998 & Barros *et al.*, 2007).

On the other hand, The increased population of spider mites in cotton is caused by the mortality of

their natural enemies, dispersal, stimulation of spider-mite reproduction, physiological and nutritional changes in the plants, and the repellent effect on predators (Degrande 1998). However, another important factor affecting this increase in spider-mite populations in soybeans is the climate, (Haile and Higley, 2003). Moreover, dry weather favors reproduction and survival of this pest (Wright *et al.*, 2006), because in such conditions the important biological control exerted by entomopathogenic fungi is almost nonexistent, (Klubertanz *et al.*, 1991).

The spider mites feed by sucking the cell contents. The chloroplasts of the affected cells are disappear and the remaining material coagulates, forming a dead white mass in one end of the cells, causing a circular injury to the surrounding cells, which appears as a chlorotic spot (Gonçalves, 1996). The object of this study was to determine the damage threshold and economic injury level (EIL) of the red spider mite *T. cucurbitacearum* (Sayed), on soybean plants.

### Material and Methods

Ecological studies conducted on the red spider mite, *T. cucurbitacearum* Magouz *et al.*, (2006) evaluated the population density of the spider mite, *T. cucurbitacearum* (Sayed) on three soybean varieties (Giza21, Giza22 and Giza111).

An area of about 350m<sup>2</sup> cultivated with soybean cultivar (Giza 111), variety in Hehyia district, Sharkia Governorate was chosen for this study. Twenty plants of twenty days old age were selected on basis of size-homogeneity and of being infested only by the red spider mite, *T. cucurbitacearum* (Sayed).

To estimate the population density of *T. cucurbitacearum* mite pest, weekly randomly

samples of twenty leaflets from twenty plants were picked weekly, from all directions, including the central branches, of each plant by using marking plants technique. During the seasons of 2015 and 2016. The samples were transported to the laboratory for inspection, and the total number of alive individuals per leaflet were recorded. The means yield quantity were estimated before and after harvest per plant.

### Statistical analysis

The effect of the population density of the mite, *T. cucurbitacearum* on the yield of soybean could be obtained through a preliminary analysis. According to Hosny *et al.*, (1972) and Hassan (1998) using the partial regression formula "C-multiplier" (Fisher 1963). Three independents were considered in the regression process ( $x_1$ ,  $x_2$  and  $x_3$ ). These represented the average number of alive adult mites per leaflet in

First peak ( $x_1$ ), in second peak ( $x_2$ ) and the average number of mite per plant during harvest time ( $x_3$ ). The yield per plant was taken as the dependent variate ( $y$ ).

### Results and discussion

The yields of twenty soybean plants were arranged descendingly according to the amount of yields and corresponding the numbers of mites during three peaks in 2015 and 2016 seasons (Table 1).

The partial regression procedure helped in obtaining information about the amount of variability in the yield that could be accounted for by all the three infestation factors combined (the explained variance). Flechtmann (1985), in his study on this pest attacking tomatoes, observed that when the infestation is high, the mites diffuse over the entire plant.

**Table1.** The yield quantity of twenty soybean plants and the corresponding population density of *T. cucurbitacearum*, during 2015 and 2016 seasons.

Rep No.	Yield in g. (Y)	2015 season			Yield in g. (Y)	2016 season

Obtained results in Table (2), indicated that the infestation factors ( $x_1$ ,  $x_2$  and  $x_3$ ) were responsible, as a group for 53.68% and of the variability in the yield weights ( $y$ ). The analysis of variance showed that the "F" value (6.18) was highly significant. Similar results were obtained in 2016 season, where the responsibility of the infestation was (80.28%), hence the significance of the "F" value was also highly significant Table 3.

To estimated the economic injury level for *T. cucurbitacearum*, firstly correcting the yield data for the effect of any two factors (as indicated by their

partial regression values) thus having in the effect of third, and so on. The three equations used in this respect were as follows:

1. For the correction of the yield weight to  $x_2$  and  $x_3$  thus leaving only the effect of the first peak infestation( $x_1$ ):  $Y_{x_1} = Y \pm [b_2 (x_2 - x_2^{-2}) + b_3 (x_3 - x_3^{-3})]$
2. For the correction of the yield weight to  $x_1$  and  $x_3$  thus leaving only the effect of the second peak infestation( $x_2$ ):  $Y_{x_2} = Y \pm [b_1 (x_1 - x_1^{-1}) + b_3 (x_3 - x_3^{-3})]$
3. For the correction of the yield weight to  $x_1$  and  $x_2$  thus leaving only the effect of the third peak infestation( $x_3$ ):  $Y_{x_3} = Y \pm [b_1 (x_1 - x_1^{-1}) + b_2 (x_2 - x_2^{-2})]$

**Table 2.** Statistical analysis (simple correlations, partial regressions and explained variance) of the relationship end effect of 3 infestation factors on the yield of 2015

So, having obtained three new corrected values for the yield of each plant, assumed to reflect the effect of only one infestation factors, it was possible to calculate a simple regression for each one. The method of "Least squares" was applied. In this way the gradual effect of infestation unit on the yield could be worked out for each factors. The main idea in this connection was to determine the slope of the regression line in each case.

But at the yield quantity and the level of infestation relationship is more or less curved rather than linear, thus a curved regression line had to be fitted. This could be accomplished by transforming

the "y" values (dependent variables) in the common regression equation ( $y = a + b x$ ) into their logarithms using the following equation:  $y = e^{- (a + b x)}$  (i.e.  $\text{Log } y = a + b x$ ).

The constants "a" and "b" in that equation were determined as follows:

$$a = 1/n \text{Log } y - b \sum x$$

$$b = \frac{n (\sum x \cdot \text{Log } y) - \sum x \cdot \sum \text{Log } y}{n \sum x^2 - (\sum x)^2}$$

Mathematically, the calculated values of (y) form a curve when they are retransformed to ordinary numbers (antilog).

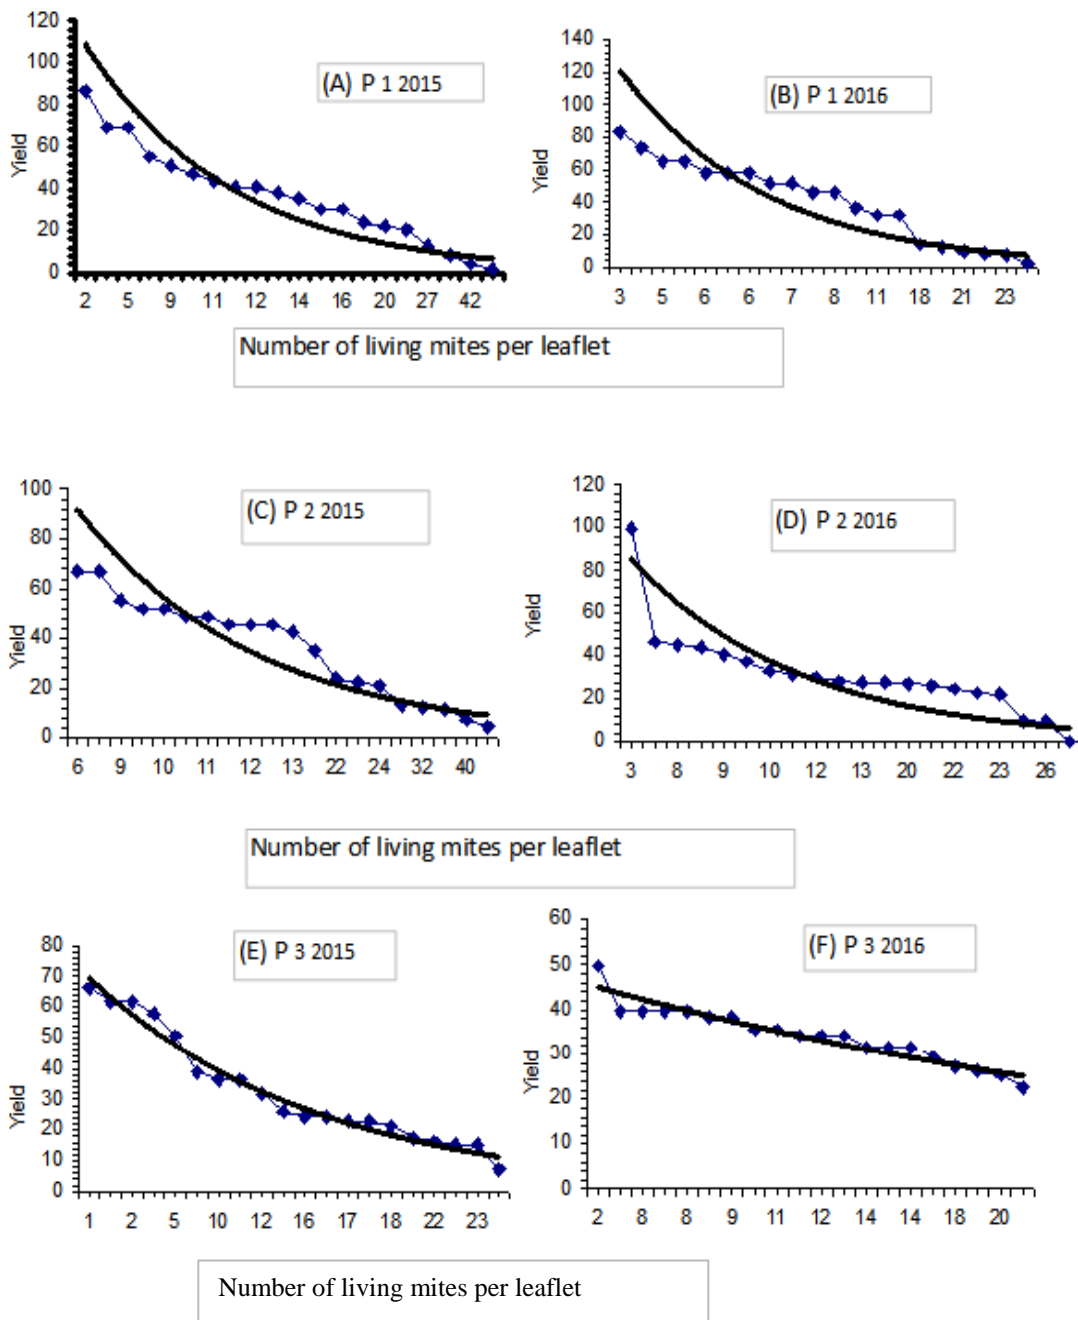

**Table 3.** Statistical analysis (simple correlations, partial regressions and explained variance) of the relationship end effect of 3 infestation factors on the yield of 2016

The population density of mite, *T. cucurbitacearum* infested soybean plant showed three peaks of activity during 2015 and 2016 seasons. The obtained results indicated that the rate of reduction in the yield of soybean differs from one infestation level to another one in the two seasons of 2015 and 2016. Tables (4&5), also it is worth to mention that the 1<sup>st</sup> peak infestation had a consistently strong yield lowering effect. Such

consistency was not quite obvious with the second and third peak of infestation (Fig 1).

These results are agree with the findings of Fadini *et al.*, (2004) and Magouz *et al.*, (2006), who mounted that the injury caused by the two-spotted spider mite results from perforation of the lower epidermis cells, and high infestations of mites reduce the rate of photosynthesis, which it may due to damaging the leaf mesophyll and causing the stomata to close.

The economic damage- level is simply the point at which the yield quantity at the upper part of the curved regression slope starts to show a significant twist. Above such a point all weight-figures are assumed to be statistically similar. The infestation level corresponding to that particular point may safely be regarded as the economic damage threshold. Practically speaking once the infestation reaches that point immediate measure of chemical control becoming inevitable in order to stop the

insignificant yield-reduction from becoming significant.

To locate precisely that point on the smoothed curve the method of Chi-square analysis termed  $r \times 2$  contingency tables with no expectation (Bailey 1959) was applied to the  $y$  data. The following example demonstrates the details of this procedure (as used to find out the damage-threshold for the first peak infestation, Table 6).

**Table 6.** The change in the soybean yield quantity by increasing the population density of *T. cucurbitacearum* during the First peak in 2015 season

Similar calculations were made to determine the threshold for second and third peaks of infestation levels. The reduction in the yield varied it may be due to different manner of infestation in each peak.

The infestation at the first peak ( $X_1$ ) showed more high effect on the yield where, ( $b = -0.0327$ ) while in other two peaks ( $X_2, X_3$ ) (regression value average "b" = - 0.335 and -0.00289) respectively during 2015. In the second season of 2016 the infestation effects could be arranged descendingly to  $X_1, X_2$  and  $X_3$  (-0.0514, -0.0280 and -0.0163), respectively.

Mathematic determination of the point at which the increase of mite number through the three peaks of infestation ( $X_1, X_2$  and  $X_3$ ) for the two seasons caused a drop in the weight of yield, the "Chi-square" analysis ( $r \times 2$ ) was applied.

Results indicated that the economic injury level was affected by the three peaks infestation peaks. In the first season of 2015 the population density during the first peak of infestation increased from 27 to 33 individuals/ 20 leaflet, resulting insignificant reduction in yield from 13.23 to 8.42 g/ plant. For the second peak the increase of infestation from 16 to 22

individuals./ 20 leaflet decreased soybean yield insignificantly from 29.71 to 18.71 g/ plant. For the third peak the increase of infestation from 3 to 9 individuals /20 leaflet decreased soybean yield insignificantly from 57.87 to 38.83 g/ plant.

The economic threshold level for three peaks in the first season was 30.29 individuals/ 20 leaflet in the first peak, while it was 27.03 and 38.83 individuals/ 20 leaflet for both second and third peaks of activity in the first season respectively. Economic injury level for three peaks during the first season (2015) which were 24.16, 26.40 and 36.34 individuals/ 20 leaflet.

In the season of 2016 for three peaks, the increase of infestation from 23 to 32 individuals/ 20 leaflet decreased soybean yield insignificantly from 7.79 to 2.69 g/ plant, in the first peak, in both second and third peaks the increase of infestation was 16-22 & 2-8 individuals/ 20 leaflet, decreased soybean yield insignificantly 35.27 to 23.97 for the second peak and 49.76 to 39.75 g/ plant for the third peak.

The economic threshold level for three peaks was 32.25, 23.97 and 31.76 individuals/ 20 leaflet. The

economic injury level for three peaks also were, 14.09, 22.47 and 29.46 individuals/ 20 leaflet. Data in (Table 7) revealed that the mean values of economic threshold and economic injury levels in

both seasons for three peaks ( $X_1$ ,  $X_2$  &  $X_3$ ) were 15.64, 12.75 and 35.30 individuals / leaflet for economic threshold level and 9.5, 12.22 and 32.9 individuals / leaflet for economic injury level.

**Table 7.** Mean values of economic threshold and economic injury levels for *T.cucurbitacearum* by using plants technique during 2015 and 2016 seasons

Seasons	Total number of mites /leaflet ( $X_1$ )		Total number of mites /leaflet ( $X_2$ )		Total number of mites /leaflet ( $X_3$ )		Total ( $X_1$ , $X_2$ & $X_3$ )		Mean	
	E.T.L	E.I.L	E.T.L	E.I.L	E.T.L	E.I.L	E.T.L	E.I.L	E.T.L	E.I.L
2015	30.29	24.16	27.03	26.40	38.83	36.34	96.15	86.9	32.05	28.97
2016	32.25	14.09	23.97	22.47	31.76	29.46	87.98	66.02	29.33	22.01
Total	31.27	19.13	25.5	24.44	70.59	65.8	127.36	109.37	42.45	36.46
Mean	15.64	9.5	12.75	12.22	35.30	32.9	63.69	54.62	21.23	18.21

Generally, the mean value of economic injury level during the first season 2015 was 28.97, while mean value of economic threshold level was 32.05 individuals / leaflet. In second season 2016 the mean value of economic injury level was 22.01 individuals /leaflet and the mean value of economic threshold level was 29.33 individuals /leaflet. ETL lies around an average infestation level of 21.23 individual per leaflet, while the EIL around an average infestation level of 18.21 individual per leaflet.

#### Acknowledgment

Thanks for our Prof. Dr. Mohamed Nada and Prof. Dr. A. Sh. Hassan for their helps in this work.

الحدود الإقتصادية الحرجة وحدود الضرر للحلم العنكبوتي *Tetranychus cucurbitacearum* علي محصول  
فول الصويا

فاطمة شحاتة قلموش

معهد بحوث وقاية النباتات - مركز البحوث الزراعية - الجيزة - مصر.

أجريت دراسات الحد الإقتصادي الحرج ومستوي الضرر الإقتصادي علي الحلم العنكبوتي ذو البقعتين *Tetranychus cucurbitacearum* علي محصول فول الصويا في مساحة ٣٥٠ متر مربع بناحية ههيا محافظة الشرقية خلال عامي (٢٠١٥ و ٢٠١٦) وذلك باتباع طريقه النباتات المعلمة.

وأوضحت النتائج أن هناك إختلافات في قيم الحدود الاقتصادية الحرجة والحدود الاقتصادية للضرر. فقد كان متوسط الحد الإقتصادي للزروات فرد / للوريقه ٣٢.٠٥ و ٢٩.٣٣ فرد / للوريقه بينما كان متوسط الضرر الاقتصادي ٢٨.٩٧ فرد / للوريقه و ٢٢.٠١ فرد / للوريقه لعامي ٢٠١٥ و ٢٠١٦ علي التوالي. وكانت متوسطات العامي لكلامن مستوي الضرر الاقتصادي ومستوي الضرر الإقتصادي ٢١.٢٣ و ١٨.٢١ فرد/ للوريقه.
